Introduction: Evidence for the use of non-anesthesiologist-administered propofol for sedation during flexible bronchoscopy is scarce. The main objective of this study was to determine whether non-anesthesiologist-administered propofol balanced sedation was related to higher transcutaneous CO₂ pressure compared with current guideline-based sedation (combination midazolam and opioid). Secondary outcomes were post-procedural recovery time, patient satisfaction and frequency of adverse events.

Methods: In this randomized controlled trial we included data from outpatients aged 18 years or older with an indication for flexible bronchoscopy in a university hospital in northern Mexico.

Results: Ninety-one patients were included: 42 in the midazolam group and 49 in the propofol group. During 60 min of transcutaneous capnometry monitoring, mean transcutaneous CO₂ pressure values did not differ significantly between groups (43.6 [7.5] vs. 45.6 [9.6] mmHg, P = .281). Propofol was related with a high Aldrete score at 5, 10, and 15 min after flexible bronchoscopy (9 [IQR 6–10] vs. 10 [9,10], P = .006; 9 [8–10] vs. 10 [IQR 9–10], P < .001 and 10 [IQR 9–10] vs. 10 [10], respectively) and with high patient satisfaction on a visual analogue scale of 1 (not satisfied) to 10 (very satisfied) (8.41 [1.25] vs. 8.97 [0.98], P = .03). Frequency of adverse events was similar among groups (30.9% vs. 22.4%, P = .47).

Conclusion: Compared with guideline-recommended sedation, non-anesthesiologist-administered propofol balanced sedation is not associated with higher transcutaneous CO₂ pressure or with more frequent adverse effects. Propofol use is associated with faster sedation recovery and with high patient satisfaction.

Clinical trial Registration: NCT02820051.

La administración de propofol por parte de no anestesiólogos durante la broncoscopia flexible no se relaciona con aumentos de la presión transcutánea de CO₂, en comparación con la sedación según las pautas: ensayo controlado aleatorizado

R E S U M E N

Introducción: Las pruebas disponibles del uso de propofol administrado por no anestesiólogos para la sedación durante la broncoscopia flexible son escasas. El objetivo principal del estudio fue determinar si la sedación equilibrada con propofol administrado por no anestesiólogos estaba relacionada con valores más altos de presión de CO₂ transcutánea, en comparación con la sedación según las pautas (una combinación de midazolam y un opiáceo). Las variables secundarias fueron el tiempo de recuperación después del procedimiento, el grado de satisfacción del paciente y la frecuencia de observación de efectos adversos.
**Introduction**

Flexible bronchoscopy (FB) is a fundamental procedure in respiratory medicine. Although FB can be performed safely without sedation, 80% of patients prefer sedation during the procedure. Current sedation and analgesia are considered the standard of care in patients without contraindication for its administration. Although midazolam is recommended for sedation in most guidelines, propofol has gained popularity, mainly due to its short recovery time. However, evidence for propofol use during FB is scarce, especially when it is not administered by an anesthesiologist.

Respiratory depression is a major concern during respiratory endoscopy. While SO2 monitoring is performed in all patients undergoing FB, CO2 monitoring is less common. For many years, CO2 measurement required an arterial blood sample; however, it can now be monitored with transcutaneous capnometry. The transcutaneous pressure of CO2 (TcPCO2) is well correlated with PaCO2, and several authors have used transcutaneous capnometry in patients undergoing different sedation protocols for endoscopic procedures; however, there is little evidence on TcPCO2 changes in patients sedated with midazolam or propofol who have received concomitant intravenous opioids (e.g., balanced sedation). In this randomized controlled trial, we evaluated ventilation response measured by transcutaneous capnometry in adult patients undergoing ambulatory FB who received non-anesthesiologist-administered propofol (NAAP) balanced sedation, and compared it with guideline-recommended sedation consisting of combination midazolam and opioid. Our primary outcome was to assess difference between groups in TcPCO2 values during and after FB. We hypothesized that TcPCO2 values would not be higher in patients who received NAAP balanced sedation. Secondary outcomes were procedural recovery time measured using the Aldrete scale, patient satisfaction, and frequency of adverse events.

**Materials and Methods**

**Patients and Procedures**

Between February and July 2014, we prospectively included ambulatory patients >18 years of age with an indication for FB. Bronchoscopy procedures were performed by respiratory and critical care medicine residents under the supervision of an associate professor in a tertiary-referral university hospital in northern Mexico. Patients with tracheostomy, known allergy to study drugs, psychiatric illness, pregnancy, American Society of Anesthesiologist physical status class IV or V, or capnometry sensor dysfunction were excluded.

Patients were assigned by block randomization to receive midazolam or propofol. In the midazolam group the initial dose was 0.05 mg/kg, and in the propofol group the starting dose was 0.1 mg/kg. Additional doses of the corresponding drug (2 mg of midazolam or 10 mg of propofol) were permitted to obtain a score of 3 to 4 on the observer’s assessment of alertness/sedation scale. All patients received nalbuphine at a starting dose of 2 mg with additional doses of 1 mg if necessary. Lidocaine spray was applied to the pharynx and also to the nasal mucosa when bronchoscope was inserted through a nostril. Endobronchial topical lidocaine was used applying the spray-as-you-go technique, at a maximum dose of 7 mg/kg. Sedation and analgesia were prescribed by the resident responsible for conducting FB and administered by an auxiliary nurse without the support of an anesthesiology specialist.

TcPCO2 measurement was carried out with the SenTec digital monitoring system (Artemis Medical, Kent, London) by applying a Stow–Severinghaus (V-Sign sensor) type sensor in the ear lobe. We monitored TcPCO2 for 1 h from the start of FB, and recorded TcPCO2 values every 5 min for the first 20 min and every 10 min up to 60 min. All patients received supplementary oxygen and were monitored with periodic non-invasive blood pressure measurements, continuous electrocardiogram, and SO2 surveillance. Residual sedation was measured on the Aldrete scale at 5, 10, and 15 min after FB. At the time of discharge from the bronchoscopy suite, satisfaction was assessed using a visual analog scale of 1 (not satisfied) to 10 (very satisfied). One investigator, blinded to the patient’s study group, recorded all procedural data. The bronchoscopist was blinded to TcPCO2 values.

**Sample Size and Statistical Analysis**

The sample was calculated for alpha 0.05, beta 0.20, standard deviation of 7.3, minimum TcPCO2 difference to detect of 5 mmHg, estimated loss to follow-up of 0.20, and two-tailed analysis. According to the above, the sample size was 42 patients per group.

We tested normal distribution with the Kolmogorov–Smirnov test. Data are shown as means and standard deviation for variables with normal distribution, and as median and interquartile range for non-normal variables. We used the t-test, the Mann–Whitney U-test, ANOVA, or chi-square as indicated. We defined a statistically significant difference as a P value <.05. The analysis was performed using SPSS version 18.0 for Windows (SPSS Inc., Chicago, IL).

**Ethical Considerations**

All participating physicians received formal training in procedural sedation with propofol from professors of the UANL.

Data are shown as mean and standard deviation. TcPCO₂: transcutaneous CO₂ pressure.

nurses was performed routinely for several years. In that setting, NAAP was feasible and safe in bronchoscopy procedures.15

In this randomized controlled trial, we compared TcPCO₂ values in patients undergoing ambulatory FB who received NAAP balanced sedation using the current guideline-recommended protocol based on a benzodiazepine plus an opioid. We found no differences between groups in TcPCO₂ levels during or after the procedure. In addition, oxygenation and vital signs did not differ significantly. To the best of our knowledge, this is the first study to investigate TcPCO₂ changes during sedation administered by respiratory medicine residents in patients who also received opioids.

A major argument for benzodiazepines use preference is the availability of an antidote to reverse excessive sedation leading to respiratory depression.14 However, our results are supported by other investigators who also suggest that propofol is at least as safe as midazolam with regard to ventilatory response. Yldizdas et al. compared children sedated using different protocols during digestive endoscopy (propofol, ketamine, and midazolam with and without fentanyl or ketamine), and found no differences in TcPCO₂ levels before or after the procedure.16 Camri et al. found high TcPCO₂ levels at 5 and 10 min after FB in patients sedated with midazolam and alfentanil in comparison with those who received propofol as monotherapy.8 More recently, Heuss et al. found no differences in TcPCO₂ between patients who received midazolam or propofol for colonoscopy.9

The dose of midazolam and propofol in the present study was lower than that used in protocols without concomitant opioid analgesia7,18 and is concordant with studies in which opioid use was permitted.9,19 The practice of adding opioids to propofol is not without its detractors; Yoon et al. comparing alfentanil
plus propofol vs. propofol alone, found no benefit in terms of cough frequency or patient and bronchoesophtist satisfaction. \textsuperscript{20} Stolz et al. found no satisfaction differences in patients sedated with midazole- lam and hydrocodone vs. propofol without an opioid; however, in their study the propofol group presented higher cough frequency. \textsuperscript{18} Finally, Clark et al. noted that propofol was better tolerated than midzolam during FB without transbronchial biopsy; they did not use opioids in any group. \textsuperscript{21} In our opinion, administration of opioids during FB sedation reduces sedation requirements. In our trial, we found no evidence of an increased incidence of hypoventilation among patients who received combination propofol plus opioid.

To the best of our knowledge, there is no firm evidence linking a particular FB sedation protocol with a higher risk of complications. In the first randomized controlled trial of midazolam and opioid vs. propofol, Stolz et al. did not find a higher complication frequency between groups; this is also true for patients with chronic obstructive pulmonary disease. \textsuperscript{18} Propofol has been related with a lower incidence of hypertension and tachycardia. \textsuperscript{15} However, in our trial we did not observe significant differences in this regard. Oztruk et al. observed an increased frequency of major arrhythmias during FB in patients who received midazolam or propofol \textsuperscript{(8% and 12%, respectively)}. \textsuperscript{17} We did not observe major arrhythmia episodes in our study, a finding that is consistent with other authors. \textsuperscript{22,23}

Recovery time after procedural sedation is an issue to consider. In the present study, patients in the propofol group had a higher Aldrete post-anesthetic recovery score. This is consistent with findings reported in the literature. A faster recovery time is one of the less controversial benefits of propofol sedation, and has even been documented in geriatric patients with hypoaalbuminemia receiving sedation due to regional anesthesia for orthopedic surgery. \textsuperscript{24} Propofolis also superior to benzodiazepines in improving cogni- tive recovery. Despite the subjective feeling of alertness, cognitive deficit is present up to 3.5 h after midazolam administration, even when patients had received flumazenil for sedation reversion. \textsuperscript{25} In contrast, patients sedated with propofol show faster improvement in cognition response. \textsuperscript{26} We did not perform a formal cognitive evaluation; however, a significantly greater proportion of patients scored at least 9 points on the Aldrete scale at 5, 15, and 30 min after propofol sedation, indicating faster global recovery after the procedure. It is important to mention that a higher total Aldrete score was mainly due to higher motor activity and conscience domain scores, while respiration and circulation domain scores did not differ between groups.

The economic impact of FB sedation is also worth examining. As far as we know, no formal cost analysis comparing propofol with midazolam has been published; however, at least one study found the cost of propofol sedation protocol to be higher. \textsuperscript{18} The higher cost of propofol must be compensated by potential savings in resources, i.e., faster post-procedural recuperation time and no anesthesiologist. Finally, we eliminated 11 (10.7%) patients from the analysis due to TCPCO\textsubscript{2} sensor problems. This proportion of technical failures was higher than the 7.2\% described by Heuss et al. in 2012. \textsuperscript{9}

This study has several limitations: (1) it was not blinded. Despite the fact that the investigator recording the information was blinded to the specific drug used during sedation, we cannot rule out bias caused by the bronchoscopist’s knowledge of the study group arm. (2) All patients were ambulatory, with low or intermediate anes-thetic risk. In accordance with current recommendations, NAAP is not indicated in high-risk patients. (3) As oral bronchoscopy insertion is associated with faster vocal cord visualization, less use of lidocaine, and no insertion failure, \textsuperscript{22} this is the route of choice for FBs in our center. (4) In our bronchoscopy service, nal- buphine is the only opioid available, therefore, our results cannot be extrapolated to other opioids. (5) All our residents were board-certified specialists in internal medicine and, as part of the Pulmonary and Critical Care sub-specialization program, had been trained in propofol use; consequently, when health specialists with other educational profiles perform NAAP, the outcomes might be different. (6) Finally, in normal clinical practice, the role of the supervising physician during FB was merely to monitor correct execution of the procedure and provide support in case of complic- ations that cannot be handled by residents. He was not required to intervene in any of the 91 endoscopic studies; however, the super- vised environment of a university hospital can increase the safety of NAAP.

In conclusion, the results of this randomized controlled trial suggest that compared with current guideline-based recommenda- tions, NAAP balanced sedation is not related to higher TCPCO\textsubscript{2} levels or a significant incidence of adverse events during or after FB when administered by pulmonary medicine and critical care residents. Propofol also seems to be associated with faster post-sedation recovery and greater patient satisfaction. Additional randomized trials, preferably double-blinded studies, are required to assess the efficacy and safety of this sedation strategy.

Funding
The equipment and drugs used in this study were provided by the Department of Pulmonary and Critical Care Medicine of the “Dr. José E. González” University Hospital. This study received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Authorship
JEG had full access to all the data in the study, takes responsi- bility for the integrity of the data and the accuracy of the data analysis, particularly any adverse effects, and assumes full respon- sibility for the integrity of the submission as a whole, from inception to published article. CA, JEG, JT, RM contributed substantially to the study design, data analysis and interpretation, and the drafting of the manuscript.

Conflict of Interest
The authors declare that they have no conflict of interest.

Acknowledgments
We thank Belia I. Gardu˜no-Chávez for her administrative sup- port in the use of propofol in the bronchoscopy suite. Also, Erik J. Rendón-Ramírez, Alexis S. Herrera-Guerra, Sergio S. López-Salazar and Diego Hernández-Velázquez for their help in coordinating and performing bronchoscopies; and Roxana Saldaña-Vázquez, for her help in reviewing the manuscript.
