Pneumothorax Following Bronchoalveolar Lavage for the Diagnosis of Non-tuberculous Mycobacterial Infection – An “Atypical” Complication of Bronchoscopy?

To the Editor,

We report the case of an 80 year-old woman who had had dry cough and wheeze for many years, presenting with increased symptoms associated with recent development of generalized weakness and weight loss. She had had several episodes of pneumonia. Previous bronchoscopy and bronchoalveolar lavage (BAL) 13 years ago was negative for acid-fast bacilli (AFB) but identified Curschmann’s spirals. Recent chest CT showed progression of consolidation in the right upper, middle and lower lobes with bilateral bronchiectasis and centrilobular micronodules in a tree-in-bud configuration. Bronchoscopy was performed for further evaluation.

Shortly after the procedure, she reported acute right-sided back pain, which responded to acetaminophen. Examination was unchanged, and chest radiography performed 3 h later did not show pneumothorax. As her pain had resolved, she was discharged home. During subsequent days, she reported fever (101–105 °F) and intermittent back and right upper quadrant pain with no dyspnea or change in cough. She was evaluated in the clinic on the fifth day after the procedure. Chest CT showed an extensive right lower and middle lobe consolidation with hydropneumothorax (Fig. 1, upper panel).

By this time, BAL smear and cultures were positive for AFB. Thoracentesis was performed, confirming an exudative pleural effusion that was lymphocyte-predominant (82% lymphocytes), and cultured no organisms. She commenced recommended treatment for non-tuberculous mycobacterium (NTM), and also treatment for presumed health-care associated pneumonia. The hydro-pneumothorax was managed without need for insertion of a pleural catheter or surgical intervention.

A diagnosis of M. avium complex was later confirmed from BAL fluid. She tolerated the NTM regimen well, reporting decreased symptoms of fever and back pain. Subsequent chest CT imaging following 3 months of treatment for NTM showed resolution of the pleural effusion and pneumothorax, and improvement in tree-in-bud appearances (Fig. 1, lower panel).

NTM disease may be associated with spontaneous pneumothorax with an incidence of 2.4%–4.1%. Mortality due to pneumothorax in such patients may be as high as 66%, compared to 8% in those without pneumothorax. Conversely, the overall risk of pneumothorax during BAL fluid collection is extremely low. In a study of 1127 BAL procedures, no patient developed pneumothorax, while in patients with Acute Respiratory Distress Syndrome, the reported incidence related to BAL is 0.9%. To our knowledge, there are no previous reports of pneumothorax due to BAL performed for the diagnosis of NTM disease.

While our patient developed back pain shortly after the procedure, chest radiography did not show pneumothorax at 3 h post-procedure. It is possible that the pneumothorax may have been too small to be initially recognized by portable chest radiography. Furthermore, a protracted history of fevers and persistent pain in the days following the procedure may have reflected aggravation of pleural inflammation, thus conceivably increasing the risk of pneumothorax during this later period.

Bronchoscopy is a commonly-used procedure in diagnosing NTM. Our case highlights an important complication in patients with NTM who undergo bronchoscopy for diagnostic confirmation. Despite the occurrence of pneumothorax, a definitive diagnosis was obtained, allowing initiation of treatment for an otherwise rapidly-progressive pulmonary infection.

4. New Outpatient Management Based on a Respiratory Virtual Clinic. An Effective Measure in Times of Austerity

Una nueva gestión ambulatoria basada en la consulta virtual de neumología. Una medida efectiva en tiempos de «austeridad»

To the Editor:

Specialized care outpatient clinics tend to be inundated by high numbers of patients referred from primary care centers (PCC).1 This overload seriously undermines the management of waiting lists and delays the evaluation of patients with severe diseases.2,3 Long waiting lists are the result of a shortage of human resources, work systems, and interdependency between PCC and specialized care facilities. In the Canary Islands, these problems are compounded by geographical obstacles and the remote location of communities. Tenerife has a surface area of 2034.38 km² and an estimated population of 906,854 inhabitants, making it the most heavily populated island in Spain. Most of the population is concentrated in 3 areas: Santa Cruz de Tenerife, San Cristobal de la Laguna and the municipalities of Arona and Adeje. The latter 2, located in the south of the island, have a resident population of 200,000 inhabitants, and the nearest tertiary hospital is at least 80 km away.

The disperse population in the south of the island and their ensuing transport difficulties led to the implementation in June 2012 of the Respiratory Virtual Clinic, the aim of which was to manage and prioritize pulmonology referrals from PCC. The Respiratory Virtual Clinic was a web-based system, offering the possibility of teleconsultation and clinical management by specialists of the respiratory system, supported by local hospitalists.4,5 Yale, Ericson, and the United Kingdom’s Primary Care Respiratory Group (PCRG) have also developed similar initiatives.6,7
