Invasive Bronchial Aspergillosis in a Hematology Patient

Aspergillosis bronquial invasiva en paciente hematológico

To the Editor,

Aspergillus is a well-characterized opportunistic fungus which often affects immunocompromised patients, particularly those with hematological cancers and severe neutropenia. The most common presentation in this patient group is angioinvasive aspergillosis. This is also the most severe form of the disease and is associated with hemorrhagic pulmonary nodules. Aspergillosis can also present in its bronchoinvasive form, manifesting as bronchiolitis, bronchopneumonia or tracheobronchitis.1

We report the case of a 52-year-old man with a diagnosis of acute myelomonocytic leukemia, receiving his second consolidation chemotherapy. He was admitted for fever and productive cough, after receiving inhaled colistin for one month for multidrug-resistant Pseudomonas aeruginosa respiratory tract colonization. We decided to suspend chemotherapy and started a diagnostic study. The chest X-ray showed no significant changes and the blood panel showed hemoglobin 10.8 g/dl, leukocytes 7.7 × 10⁹ µl⁻¹ and 68% neutrophils. A repeat sputum culture was positive for multidrug-resistant Pseudomonas aeruginosa, so colistin treatment was maintained. In view of persistent symptoms, a chest computed tomography (CT) was performed, revealing parietal thickening of the carina and the left main bronchus, extending to the upper left lobe bronchus, and partially to the left lower lobe bronchus. A soft tissue mass was seen protruding into the lumen of the upper lobe bronchus (Fig. 1A–C). Pulmonary parenchyma was unchanged (Fig. 1).

In an immunosuppressed patient, the first diagnosis to consider is fungal infection (aspergillosis, candidiasis or mucormycosis). Fiberoptic bronchoscopy was performed, which showed whitish membranes in the trachea and in both main bronchi. Biopsies were obtained and were found to contain fibrinous, inflammatory membranes and fragments of bronchial mucosa with mature squamous metaplasia and neovascularization, with no evidence of malignancy. Aspergillus fumigatus was isolated from the culture of the biopsy samples, and treatment began with voriconazole, with gradual resolution of fever and cough. The follow-up CT, 2 months after treatment, showed reduced tracheobronchial wall thickening (Fig. 1D).

Tracheobronchitis caused by Aspergillus presents in 3 forms: obstructive bronchial aspergillosis, consisting of mucus plugs due to overgrowth of hyphae with minor mucosa involvement; ulcerative tracheobronchitis; and pseudomembranous tracheobronchitis, which is associated with extensive inflammation and invasion of the tracheobronchial tree, in the presence of pseudomembranes. In view of CT and fiberoptic bronchoscopy findings, our case was classified as pseudomembranous tracheobronchitis.

Our case is of interest, since Aspergillus tracheobronchitis is an entity generally seen in patients with AIDS and lung transplants.2,3 It is very uncommon in patients with hematological cancers, who tend to develop other forms of aspergillosis due to their severe neutropenia.1,4

We put forward the hypothesis that the use of inhaled antibiotics alters the normal flora of the airways, thus increasing the possibility of developing Aspergillus infection.3

Fig. 1. (A–C) CT from diagnostic study, showing considerable thickening of the left main bronchus, extending to the upper left lobe bronchus. (D) Follow-up CT, 2 months after treatment, showing reduced thickening in the wall of the left main bronchus and left upper lobe bronchus, and resolution of the soft tissue mass that was invading the left upper lobe bronchus.

Association of Three Developmental Lung Anomalies in an Adult

Asociación de tres anomalías del desarrollo pulmonar en un adulto

To the Editor,

Congenital lung and mediastinum malformations represent a wide and varied spectrum of development abnormalities, including cystic adenomatoid malformation (CAM), pulmonary sequestration, congenital lobar emphysema, bronchogenic cyst (BC), esophageal duplication cyst (EDC), and neurenteric cysts. These congenital malformations occur when the development of the respiratory system is altered. Differentiation begins after the third week of gestation, and 4 different stages have been defined: the embryonic phase, the pseudoglandular phase, the canalicular phase and the saccular phase. Altered development at any of these stages may cause bronchopulmonary malformations. Lung development is closely related with the development of the foregut, and for this reason these malformations commonly occur along with extrapulmonary congenital abnormalities. In the past, congenital

Fig. 1. (A) Chest X-ray showing nodular lesions in left upper lobe (LUL) (short arrow) and basal radiopacity with reduced blood perfusion (long arrows). (B) Axial computed tomography (CT) image of chest, confirming the presence of a cystic-type lesion in the left upper lobe, with typical fluid–fluid level. The supernatant (short arrow) has a density similar to water, while the density of the fluid in the lower part (long arrow) is calcific (calcium milk). (C) MiniIP (minimum intensity axial projection) CT image showing a well-defined multilocular lesion (arrows), suggestive of malformation, in the left lower lobe basal segments, not communicating with the airway. (D) MiniIP coronal reconstruction showing a mild mass effect on the mediastinum towards the right side (short arrows). Note the nodular lesion in the LUL (long arrow). (E) Axial CT image showing a cystic lesion in the posterior mediastinum, adjacent to the anterior thoracic esophageal margin (arrows).
